Host-mediated lung inflammation is present,¹ and drives mortality,² in critical illness caused by Covid-19. Host genetic variants associated with critical illness may identify mechanistic targets for therapeutic development.³ Here we report the results of the GenOMICC (Genetics Of Mortality In Critical Care) genome-wide association study (GWAS) in 2244 critically ill Covid-19 patients from 208 UK intensive care units (ICUs). We identify and replicate novel genome-wide significant associations, on chr12q24.13 (rs10735079, $p=1.65\times 10^{-8}$) in a gene cluster encoding antiviral restriction enzyme activators (*OAS1*, *OAS2*, *OAS3*), on chr19p13.2 (rs2109069, $p=2.3\times 10^{-12}$) near the gene encoding tyrosine kinase 2 (*TYK2*), on chr19p13.3 (rs2109069, $p=3.98\times 10^{-12}$) within the gene encoding dipeptidyl peptidase 9 (*DPP9*), and on chr21q22.1 (rs2236757, $p=4.99\times 10^{-8}$) in the interferon receptor gene *IFNAR2*. We identify potential targets for repurposing of licensed medications: using Mendelian randomisation we found evidence in support of a causal link from low expression of *IFNAR2*, and high expression of *TYK2*, to life-threatening disease; transcriptome-wide association in lung tissue revealed that high expression of the monocyte/macrophage chemotactic receptor *CCR2* is associated with severe Covid-19. Our results identify robust genetic signals relating to key host antiviral defence mechanisms, and mediators of inflammatory organ damage in Covid-19. Both mechanisms may be amenable to targeted treatment with existing drugs. Large-scale randomised clinical trials will be essential before any change to clinical practice.

Since critical illness in Covid-19 is caused, in part, by inflammatory injury affecting the lungs and lung blood vessels,¹ there are at least two distinct biological components to mortality risk: susceptibility to viral infection, and propensity to develop harmful pulmonary inflammation. Susceptibility to life-threatening infections⁴ and immune-mediated diseases are both strongly heritable. In particular, susceptibility to respiratory viruses⁵ such as influenza⁶ is heritable and known to be associated with specific genetic variants.⁷ In Covid-19, one genetic locus, in 3p21.31, has been repeatedly associated with hospitalisation.^{8,9} As with other viral illnesses,¹⁰ there are several examples of loss-of-function variants affecting essential immune processes that lead to severe disease in young people: for example *TLR7*,¹¹ and several

genes implicated in type 1 interferon signalling including the receptor subunit *IFNAR2*.¹² Genome-wide studies have the potential to reveal completely new molecular mechanisms of critical illness in Covid-19, which may provide therapeutic targets to modulate the host immune response to promote survival.³

There is now strong evidence that critical illness caused by Covid-19 is qualitatively different from mild or moderate disease, even among hospitalised patients. There are multiple distinct disease phenotypes with differing patterns of presenting symptoms¹³ and marked differential responses to immunosuppressive therapy.² In patients without respiratory failure, there is a trend towards harm from treatment with corticosteroids, whereas among patients with critical respiratory

A list of affiliations appears at the end of the paper.

Article

failure, there is a very substantial benefit.² On this basis, we consider patients with critical Covid-19 respiratory failure to have distinct pathophysiology.

In the UK, the group of patients admitted to critical care is relatively homogeneous, with profound hypoxaemic respiratory failure being the archetypal presentation.¹⁴ The active disease process in these patients is strikingly responsive to corticosteroid therapy¹⁵ and is characterised by pulmonary inflammation including diffuse alveolar damage, lung macrophage/monocyte influx, mononuclear cell pulmonary artery vasculitis and microthrombus formation.^{1,16}

Host-directed therapies have long been an aspiration for the treatment of severe disease caused by respiratory viruses.¹⁷ Identification of genetic loci associated with susceptibility to Covid-19 may lead to specific targets for repurposing or drug development.³

The GenOMICC (Genetics Of Mortality In Critical Care, genomicc.org) study has been recruiting patients with critical illness syndromes, including influenza, sepsis, and emerging infections, for 5 years. In order to better understand the host mechanisms leading to life-threatening Covid-19, we performed a genome-wide association study comparing critically ill patients with Covid-19 with controls from population genetic studies in the UK.

Results

Critically ill cases were recruited through the GenOMICC study in 208 UK Intensive Care Units and hospitalised cases through the International Severe Acute Respiratory Infection Consortium (ISARIC) Coronavirus Clinical Characterisation Consortium (4C) study.

DNA was extracted from whole blood and array-based genome-wide genotypes of good quality obtained for 2734 unique individuals (Materials & Methods). Genetic ancestry was inferred using principal component analyses and individuals from the 1000 Genomes project as population references (Materials & Methods). After quality control and matching to ancestry groups, 2244 individuals were included for GWAS analysis. Clinical and demographic features of these cases are shown in Extended Data Table 1. Additional clinical details for a subset of 1069 cases for whom additional data was available is presented in Supplementary Figures 7–13 and Supplementary Table 2. Cases were representative of the UK critically ill population.¹⁴ Imputation in this multi-ancestry cohort was performed using the TOPMed reference panel.

Ancestry-matched controls were selected from the large population-based cohort UK Biobank (5 controls to 1 case). Controls with a known positive Covid-19 test were excluded. The inevitable presence of individuals in the control group, who may exhibit the critical illness phenotype if exposed to SARS-CoV-2 is expected to bias any associations towards the null. GWAS was carried out separately by ancestry group using logistic regression in PLINK and accounting for age, sex, postal code deprivation decile and principal components of ancestry. As well as several standard filters to minimise spurious associations (Materials & Methods), whole genome sequencing of a subset of 1613 cases was used to filter out variants likely to have been badly-called or imputed; 83937 out of the 4469187 imputed variants that passed other quality control filters after GWAS were thus removed. There was a high level of residual inflation in the South Asian and East Asian ancestry groups, rendering results in these subgroups unreliable (Extended Data Figure 1, Supplementary Figure 4). The largest ancestry group contained 1676 individuals of European descent (EUR); this group was used for the primary analyses presented below.

GWAS results

In the primary analysis (GenOMICC European cases vs. UK Biobank controls), following linkage disequilibrium-based clumping,

15 independent association signals were genome-wide significant at $p < 5 \times 10^{-8}$ (Supplementary Figure 1). Eight of these were successfully validated in GWAS using two independent population genetic studies (100,000 genomes and Generation Scotland) as controls (Table 1) and hence were taken forward for replication. A sex-specific GWAS among this group found no sex-specific associations (Supplementary Table 1). Trans-ethnic meta-analysis did not reveal additional associations (Supplementary Figure 3).

Replication

Since no study of critical illness in Covid-19 of sufficient size is available, replication was sought in a meta-analysis of data from 2415 hospitalised Covid-19 cases and 477741 population controls from the Covid-19 Host Genetics Initiative (HGI, mixed ancestry, with UK Biobank cases and controls excluded) and 1128 cases and 679531 controls in the 23andMe Inc “broad respiratory phenotype” (EUR ancestry), which includes cases reported being placed on a ventilator, being administered oxygen, or having pneumonia versus controls who did not report positive tests. In addition to the locus on chr3 already reported ($rs73064425$, OR=2.14, discovery $p = 4.77 \times 10^{-30}$), we found robust replication for the novel associations in four loci from GenOMICC: a locus on chr12 in the *OAS* gene cluster ($rs74956615$, OR=1.59, discovery $p = 1.65 \times 10^{-8}$), near *TYK2* on chr19 ($rs74956615$, OR=1.4, discovery $p = 2.3 \times 10^{-8}$), in *DPP9* on chr19 ($rs2109069$, OR=1.36, discovery $p = 3.98 \times 10^{-12}$), and a locus on chromosome 21, containing the gene *IFNAR2* ($rs2236757$, OR=1.28, discovery $p = 4.99 \times 10^{-8}$) (Figure 1, Extended Data Table 2).

Three variants, all in a region of chromosome 6 in which population stratification is difficult to control (the major histocompatibility complex), did not replicate (Extended Data Table 2, Supplementary Figure 2). Further studies will be required to determine whether these associations are real.

To increase power for exploratory analyses, inverse-variance meta-analysis was performed between GenOMICC critically ill EUR ($n_{cases} = 1676$, $n_{controls} = 8380$), HGI hospitalised Covid-19 vs population (B2, version 2) without UKBioBank ($n_{cases} = 2415$, $n_{controls} = 477741$) and the 23andMe broad respiratory phenotype ($n_{cases} = 1128$, $n_{controls} = 679531$). This revealed one additional (unreplicated) locus in CCHCR1 at genome-wide significance (using a more stringent threshold of $p < 10^{-8}$ in view of the absence of replication opportunities for the meta-analysis) (Table 2).

Mendelian randomisation

Mendelian randomisation provides evidence for a causal relationship between an exposure variable and an outcome, given a set of well-characterised assumptions.¹⁸ We employed two-sample summary-data Mendelian randomisation to assess the evidence in support of causal effects of RNA expression (GTEx v7, whole blood) of various genes on the odds of critical Covid-19.

We specified an *a priori* list of target genes that relate to the mechanism of action of many host-targeted drugs that have been proposed for the treatment of Covid-19 (Supplementary Table 3). Seven of these targets had a suitable locally-acting expression quantitative trait locus (eQTL) in GTEx(v7). Of these, *IFNAR2* remained significant after Bonferroni correcting for multiple testing for 7 tests ($\beta = 1.49$, standard error 0.52, $p = 0.0043$; Supplementary Table 4). There was equivocal evidence of heterogeneity (HEIDI¹⁹ $p = 0.015$), indicating that the effect of this variant on critical illness in Covid-19 may be mediated through another mechanism, which may lead to an under- or over-estimation of the effect of *IFNAR2* expression on risk of critical illness.

We then performed transcriptome-wide Mendelian randomisation to quantify support for *unselected* genes as potential therapeutic targets. Instruments were available for 4,614 unique Ensembl gene IDs.

No genes were statistically significant after correcting for multiple comparisons in this analysis (4,614 tests). After conservative filtering for heterogeneity (HEIDI $p > 0.05$), the smallest Mendelian randomisation $p = 0.00049$ for a variant at chr19:10466123 affecting expression of *TYK2*. 9 other genes with nominally significant Mendelian randomisation p-values ($p < 0.0051$) were also taken forward for further analysis (Supplementary Table 5).

To replicate these findings, we tested for external evidence using a separate eQTL dataset (eQTLgen)²⁰ and GWAS (HG1 B2, excluding UK Biobank). Mendelian randomisation signals with consistent directions of effect were significant for *IFNAR2* ($p = 7.5 \times 10^{-4}$) and *TYK2* ($p = 5.5 \times 10^{-5}$; Supplementary Table 6).

Transcriptome-wide association study

We performed transcriptome-wide association study (TWAS)^{21,22} to link GWAS results to tissue-specific gene expression data by inferring gene expression from known genetic variants that are associated with transcript abundance (eQTL). For this analysis we used GTEx v8 data for two disease-relevant tissues chosen *a priori*: whole blood and lung (Figure 2). We selected genes with $p < 0.05$ in these tissues and performed a combined meta-TWAS analysis,²³ incorporating eQTL data from other tissues in GTEx, to optimise power to detect differences in predicted expression in lung or blood.

We discovered 5 genes with genome-wide significant differences in predicted expression compared to controls (Supplementary Table 7). This included 4 genes with differential predicted expression in lung tissue (3 on chr3: *CCR2*, *CCR3* and *CXCR6*, and one on chr5: *MTA2B*; Supplementary Tables 8-10).

We used meta-analysis by information content (MAIC)²⁴ to put these results in the context of existing biological knowledge about host-virus interactions in Covid. We combined the top 2000 genes in meta-TWAS with previous systematically-compiled experimental evidence implicating human genes in SARS-CoV-2 replication and host response. MAIC derives a data-driven weighting for each of a range of experimental data sources in the form of gene lists, and outperforms other approaches to providing a composite of multiple lists.²⁴ We found that the GenOMICC TWAS results had greater overlap with results from transcriptomic, proteomic and CRISPR studies of host genes implicated in Covid-19 than any other data source (Extended Data Figure 2).

Genetic correlations

We used the high-definition likelihood (HDL) method²⁵ to provide an initial estimate the SNP-based heritability (the proportion of phenotypic variance that is captured by additive effects at common SNPs) for severe Covid-19 to be 0.065 (SE = 0.019). We were not able to detect a significant signal for heritability in two additional analyses: firstly, using controls from the 100,000 genomes project (in which matching to the GenOMICC cases is less close, which may limit heritability estimation) and secondly, in a smaller GWAS comparing some GenOMICC cases with UK Biobank controls, using matching of BMI and age where possible. This second analysis was less powerful because of the lack of close matches for many cases ($n_{\text{cases}} = 1260$; $n_{\text{controls}} = 6300$; Supplementary Figure 14). Including rare variants in future analyses, with larger numbers of cases, will provide a more comprehensive estimate of heritability. We also tested for genetic correlations with other traits, that is, the degree to which the underlying genetic components are shared with severe Covid-19. Using the HDL method, we identified significant negative genetic correlations with educational attainment and intelligence. Significant positive genetic correlations were detected for a number of adiposity phenotypes including body mass index and leg fat (Supplementary Figure 19).

Consistent with GWAS results from other infectious and inflammatory diseases, there was a significant enrichment of strongly associated variants in promoters and enhancers,²⁶ particularly those identified by the ExAC study as under strong evolutionary selection (Supplementary Figure 18).²⁷ The strongest tissue type enrichment was in spleen (which may reflect enrichment in immune cells), followed by pancreas (Supplementary Figure 20).

Discussion

We have discovered and replicated significant genetic associations with life-threatening Covid-19 (Figure 1). Our focus on critical illness increases the probability that some of these associations relate to the later, immune-mediated phase of disease associated with respiratory failure requiring invasive mechanical ventilation.² Importantly, the GWAS approach is unbiased and genome-wide, enabling the discovery of completely new pathophysiological mechanisms. Because genetic variation can be used to draw a causal inference, genetic evidence in support of a therapeutic target substantially improves the probability of successful drug development.²⁸ In particular, Mendelian randomisation occupies a unique position in the hierarchy of clinical evidence.²⁹

Patients admitted to intensive care units in the UK during the first wave of Covid-19 were, on average, younger and less burdened by comorbid illness than the hospitalised population.¹⁴ The population studied here are defined by their propensity to critical respiratory failure due to Covid-19. GenOMICC recruited in 208 intensive care units (covering > 95% of UK ICU capacity), ensuring that a broad spread across the genetic ancestry of UK patients was included (Extended Data Figure 3).

For external replication, the nearest comparison is the hospitalised vs population analysis in the Covid-19 Host Genetics initiative, and the 23andMe broad respiratory phenotype, which have been generously shared with the international community. Likewise, full summary statistics from GenOMICC have been made immediately openly available at genomicc.org/data.

Despite the differences in case definitions, novel associations from our study of critical illness replicate robustly in combined data from hospitalised case studies (Extended Data Table 2). Separately, the Mendelian randomisation results implying a causal role for *IFNAR2* and *TYK2* are also statistically significant in confirmatory analyses. Our findings reveal that critical illness in Covid-19 is related to at least two biological mechanisms: innate antiviral defences, which are known to be important early in disease (*IFNAR2* and *OAS* genes), and host-driven inflammatory lung injury, which is a key mechanism of late, life-threatening Covid-19 (*DPP9*, *TYK2* and *CCR2*).²

Interferons are canonical host antiviral signalling mediators, and stimulate release of many essential components of the early host response to viral infection.³⁰ Consistent with a beneficial role for type I interferons, increased expression of the interferon receptor subunit *IFNAR2* reduced the odds of severe Covid-19 with Mendelian randomisation discovery $p = 0.0043$ (7 tests); replication $p = 7.5 \times 10^{-4}$ (1 test). Within the assumptions of Mendelian randomisation, this represents evidence for a protective role for *IFNAR2* in Covid-19. Rare loss-of-function mutations in *IFNAR2* are associated with severe Covid-19¹² and many other viral diseases.^{31,32} This suggests that administration of interferon may reduce the probability of critical illness in Covid-19, but our evidence cannot distinguish *when* in illness such a treatment may be effective. Exogenous interferon treatment did not reduce mortality in hospitalised patients in a large scale clinical trial,³³ suggesting that this genetic effect may be mediated during the early phase of disease when viral load is high.

The variant rs10735079 (chr12, $p = 1.65 \times 10^{-8}$) lies in the interferon-inducible oligoadenylate synthetase (OAS) gene cluster (*OAS1*, *OAS2* and *OAS3*; Figure 1). Our TWAS detected significant associations with predicted expression of *OAS3* (Figure 2). *OAS1* variants were implicated

Article

in susceptibility to SARS-CoV in candidate gene association studies in Vietnam³⁴ and China.³⁵ These genes encode enzymes which produce a mediator (2',5'-oligoadenylate, 2'-5A) which activates an effector enzyme, RNase L. RNase L degrades double-stranded RNA,³⁶ a replication intermediate of coronaviruses.³⁷ The betacoronaviruses OC43 and MHV make viral phosphodiesterases that cleave the host antiviral mediator 2'-5A,³⁸ but SARS-CoV-2 is not known to have this ability. The OAS genes therefore also provide a potential therapeutic target: endogenous phosphodiesterase 12 (PDE-12) activity degrades the host antiviral mediator 2'-5A. Therapeutic PDE-12 inhibitors are available, and augment OAS-mediated antiviral activity.³⁹

The association in 19p13.3 (rs2109069, $p = 3.98 \times 10^{-12}$) is an intronic variant in the gene encoding dipeptidyl peptidase 9 (*DPP9*). Variants in this locus are associated with idiopathic pulmonary fibrosis.⁴⁰ *DPP9* encodes a serine protease with diverse intracellular functions, including cleavage of the key antiviral signalling mediator CXCL10,⁴¹ and key roles in antigen presentation,⁴² and inflammasome activation.⁴³

Since opportunities for therapeutic intervention, particularly experimental therapy, are more abundant in later, more severe disease, it is important that our results also reveal genes that may act to drive inflammatory organ injury. *TYK2* is one of 4 gene targets for JAK inhibitors such as baricitinib,⁴⁴ one of the nine candidate drugs we used in the creation of our *a priori* target list (Supplementary Table 3). The association between *TYK2* expression and critical illness was also confirmed in an external dataset.

We replicate the finding of Ellinghaus *et al.* at 3p21.31.⁸ The extremely small p-value at this locus ($p=4.77 \times 10^{-30}$) may reflect the large size of our study, and our focus on extreme severity, since we see a larger effect size in GenOMICC than in the replication studies (Extended Data Figure 4). A number of genes in this locus could plausibly explain an association. Our systematic review and meta-analysis of experimental data on betacoronavirus infection from other sources provides moderate biological support for *FYCO1*, although this additional information comes mostly from *in vitro* model systems.⁴⁵ Our TWAS results show that variants in this region confer genome-wide significant differences in predicted expression of *CXCR6*, *CCR2* and *CCR3* (Figure 2a); it is likely that one, but not all of these genes is an important mediator of critical illness.

Association with critical illness for genotype-inferred *CCR2* (CC-chemokine receptor 2) expression is particularly strong in lung tissue (Figure 2b). *CCR2* promotes monocyte/macrophage chemotaxis towards sites of inflammation, and there is increased expression of the canonical ligand for *CCR2* (monocyte chemoattractant protein/MCP-1), in bronchoalveolar lavage fluid from the lungs of Covid-19 patients during mechanical ventilation.⁴⁶ Circulating MCP-1 concentrations are associated with more severe disease.⁴⁷ Anti-*CCR2* monoclonal antibody therapy in treatment of rheumatoid arthritis is safe.⁴⁸

The *ABO* locus was also previously associated with Covid-19,⁸ but was not genome-wide significant in the GenOMICC critically ill cohort. Interestingly there is a signal close to genome-wide significance at this locus in the combined meta-analysis (Figure 1), suggesting that this variant may be associated with susceptibility to Covid-19, but not critical illness (Extended Data Figure 4).

Analysis of shared heritability highlights a positive correlation with adiposity. This does not imply a causal relationship, as a number of biases may be at play, but may reflect a combination of two effects: firstly, increased BMI and lower socio-economic status are strong risk factors for severe Covid-19,¹⁴ and secondly, UK Biobank participants are disproportionately drawn from social groups in which obesity is under-represented compared to the general population.⁴⁹

Because of the urgency of completing and reporting this work, we have drawn controls from population genetic studies with systematic differences in population structure, demographics and comorbid illness, who were genotyped using different technology from the cases. Residual confounding is reflected in the genomic inflation ($\lambda_{0.5}$) value

of 1.099 for the primary analysis (Extended Data Figure 1). We mitigated the consequent risk of false-positive associations driven by genotyping errors by genotyping the majority of our subjects using two different methods (microarray and whole-genome sequencing), and by verifying significant associations using two additional control groups (100,000 genomes and Generation Scotland). The success of these mitigations is demonstrated by robust replication of our sentinel SNPs in external studies. Our meta-analysis, combining GenOMICC with multiple additional sources of genome-wide associations, has a reasuring $\lambda_{0.5} = 1.017$ (Extended Data Figure 1).

There is an urgent need to deepen these findings through further studies. Our MAIC results show that highly ranked genes in GenOMICC are more likely to be implicated in Covid in other studies (Extended Data Figure 2). We continue to recruit to the GenOMICC study, in the expectation that additional associations exist and can be detected with larger numbers of cases. Future studies using whole genome sequencing will search the rarer end of the allele frequency spectrum for variants increasing susceptibility. Effect sizes are likely to be greater in GenOMICC because the cohort is strongly enriched for immediately life-threatening disease in patients who are either receiving invasive mechanical ventilation, or considered by the treating physicians to be at high risk of requiring mechanical support.

We have discovered new and highly plausible genetic associations with critical illness in Covid-19. Some of these associations lead directly to potential therapeutic approaches to augment interferon signalling, antagonise monocyte activation and infiltration into the lungs, or specifically target harmful inflammatory pathways. While this adds substantially to the biological rationale underpinning specific therapeutic approaches, each treatment must be tested in large-scale clinical trials before entering clinical practice.

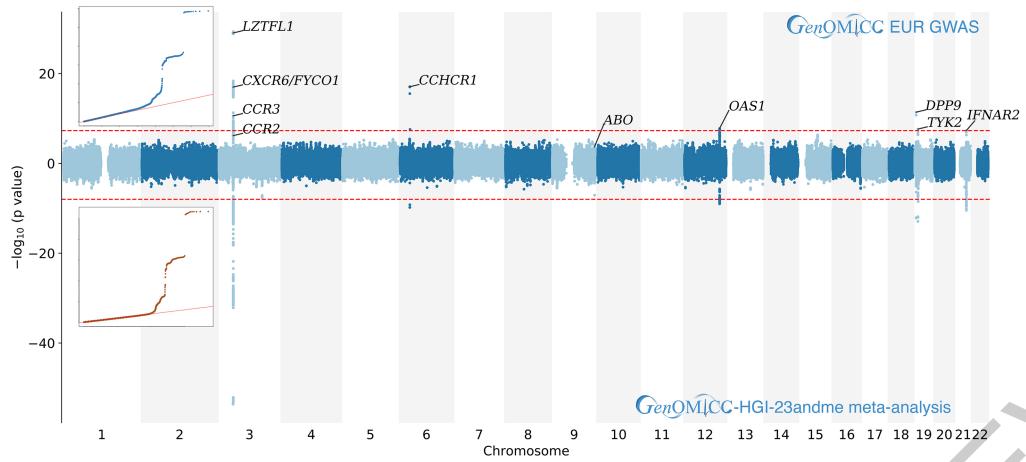

Fig. 1 | Discovery GWAS and meta-analysis results. Miami plot showing p-values for GenOMICC GWAS in EUR (after validation, top panel) and meta-analysis including patients from the Covid-19 Host Genetics Initiative and 23andMe (bottom panel). Uncorrected p-values from GWAS analysis are shown. In upper (GenOMICC) panel, red horizontal line shows genome-wide significance for common variants at $-\log_{10}(5 \times 10^{-8})$; in lower (meta-analysis)

panel, red horizontal line shows a more stringent genome-wide significance threshold for meta-analysis variants at $-\log_{10}(10^{-8})$. Quantile-quantile (QQ) plots are inset showing observed vs expected p-values to show genomic inflation (λ) for each analysis: GenOMICC EUR $\lambda = 1.099$; GenOMICC-HGI-23m meta-analysis $\lambda = 1.017$. Full QQ plots are in Extended Data Figure 1.

Fig. 2 | Summary of TWAS results. *a*, Gene-level Manhattan plot showing raw p-value results from meta-TWAS analysis across tissues (see Methods). Red horizontal line shows gene-level genome-wide significance at $-\log_{10}(5 \times 10^{-6})$. *b*,

z-scores showing direction of effect for genotype-inferred expression of transcripts encoding protein-coding genes in lung tissue (GTEX v8). Red highlighting indicates genome-wide significance at $p < 5 \times 10^{-6}$.

Table 1 | Lead variants from independent genome-wide significant regions

chr:pos - chromosome and position of the top SNP (build 37); Risk - risk allele; Alt - other allele; RAF - risk allele frequency; OR - effect size (odds ratio) of the risk allele in the GenOMICC EUR analysis; CI - 95% confidence interval for the odds ratio in the GenOMICC EUR cohort; P - p-value, Locus – gene nearest to the top SNP. Subscript identifiers indicate the cohorts used for cases: gcc - GenOMICC EUR; and controls: ukb - UK Biobank; gs - Generation Scotland; 100k - 100,000 genomes.

Article

Table 2 | Meta-analysis of overlapping SNPs between GenOMICC (EUR) and HGI (hospitalized Covid-19 vs. population) and 23andMe studies

Since this is a meta-analysis of all available data, external replication cannot be attempted, so SNPs are included in this table if they meet a more stringent p-value threshold of $p < 10^{-9}$. SNP – the strongest SNP in the locus; ; Risk – risk allele; Alt - alternative allele; OR - odds ratio of the risk allele; CI - 95% confidence interval for odds ratio; Locus – gene nearest to the top SNP. Subscript identifiers show gcc - GenOMICC study, European ancestry, comparison with UK Biobank; meta - combined meta-analysis of all three studies (GenOMICC, HGI and 23andMe) for cases of European ancestry.

Methods

Recruitment of cases

2,636 patients recruited to the GenOMICC study (genomicc.org) had confirmed Covid-19 according to local clinical testing and were deemed, in the view of the treating clinician, to require continuous cardiorespiratory monitoring. In UK practice this kind of monitoring is undertaken in high-dependency or intensive care units. An additional 135 patients were recruited through ISARIC4C (isaric4c.net) - these individuals had confirmed Covid-19 according to local clinical testing and were deemed to require hospital admission. Both studies were approved by the appropriate research ethics committees (Scotland 15/SS/0110, England, Wales and Northern Ireland:19/WM/0247). Current and previous versions of the study protocol are available at genomicc.org/protocol. All participants gave informed consent.

Genotyping

DNA was extracted from whole blood using Nucleon Kit (Cytiva) with the BACC3 protocol. DNA samples were re-suspended in 1 ml TE buffer pH 7.5 (10mM Tris-Cl pH 7.5, 1mM EDTA pH 8.0). The yield of the DNA was measured using Qubit and normalised to 50ng/ μ l before genotyping.

Genotyping was performed using the Illumina Global Screening Array v3.0 + multi-disease beadchips (GSAMD-24v3-0-EA) and Infinium chemistry. In summary this consists of three steps: (1) whole genome amplification, (2) fragmentation followed by hybridisation, and (3) single-base extension and staining. For each of the samples, 4..l of DNA normalised to 50ng/ μ l was used. Each sample was interrogated on the arrays against 730,059 SNPs. The arrays were imaged on an Illumina iScan platform and genotypes were called automatically using GenomeStudio Analysis software v2.0.3, GSAMD-24v3-0-EA_20034606_A1.bpm manifest and cluster file provided by manufacturer.

In 1667 cases, genotypes and imputed variants were confirmed with Illumina NovaSeq 6000 whole genome sequencing. Samples were aligned to the human reference genome hg38 and variant called to GVCF stage on the DRAGEN pipeline (software v01.011.269.3.2.22, hardware v01.011.269) at Genomics England. Variants were genotyped with the GATK GenotypeGVCFs tool v4.1.8.1,⁵⁰ filtered to minimum depth 8X (95% sensitivity for heterozygous variant detection,⁵¹) merged and annotated with allele frequency with bcftools v1.10.2.

Quality control

Genotype calls were carefully examined within GenomeStudio using manufacturer and published⁵² recommendations, after excluding samples with low initial call rate (<90%) and reclustering the data thereafter. Briefly, X and Y marker calls were all visually inspected and curated if necessary, as were those for autosomal markers with minor allele frequency >1% displaying low Gentrain score, cluster separation, and excess or deficit of heterozygous calls. Genotype-based sex determination was performed in GenomeStudio and samples excluded if not matching records expectation. Five individuals with XYY genotypes were also detected and excluded for downstream GWAS analyses. Genotypes were exported, in genome reference consortium human build 37 (GRCh37) and Illumina "source" strand orientation, using the GenotypeStudio plink-input-report-plugin-v2.1-4. A series of filtering steps was then applied using PLINK 1.9 leaving 2790 individuals and 479095 variants for further analyses (exclusion of samples with call rate < 95%, selection of variants with call rate > 99% and minor allele frequency (MAF) >1% and final samples selection using a call rate > 97%).

Kinship

Kinship and ancestry inference were calculated following UK Biobank⁴⁹ and 1M veteran program.⁵³ First King 2.1⁵⁴ was used to find duplicated individuals which have been recruited by two different routes. The analysis flagged 56 duplicated pairs, from which one was removed

according to genotyping quality (GenomeStudio p50GC score or/and individual call rate). This leaves a set of 2734 unique individuals.

Regions of high linkage disequilibrium (LD) defined in the UK Biobank⁴⁹ were excluded from the analysis, as well as SNPs with MAF<1% or missingness >1%. King 2.1 was used to construct a relationship matrix up to 3rd degree using the King command --kinship --degree 3 and then the function largest_independent_vertex_set() from the igraph tool <http://igraph.sf.net> was used to create a first set of unrelated individuals. Principal component analysis (PCA) was conducted with gcta 1.9⁵⁵ in the set of unrelated individuals with pruned SNPs using a window of 1000 markers, a step size of 80 markers and an r^2 threshold of 0.1. SNPs with large weights in PC1, PC2 or PC3 were removed, keeping at least 2/3 of the number of pruned SNPs to keep as an input of the next round of King 2.1. The second round of King 2.1 was run using the SNPs with low weights in PC1, PC2 and PC3 to avoid overestimating kinship in non-European individuals. After this round 2718 individuals were considered unrelated up to 3rd degree.

Genetic ancestry

Unrelated individuals from the 1000 Genome Project dataset were calculated using the same procedure described above, and both datasets were merged using the common SNPs. The merged genotyped data was pruned with plink using a window of 1000 markers a step size of 50 and a r^2 of 0.05, leaving 92K markers that were used to calculate the 20 first principal components with gcta 1.9. Ancestry for GenOMICC individuals was inferred using ADMIXTURE⁵⁶ populations defined in 1000 genomes. When one individual had a probability >80% of pertaining to one ancestry, then the individual was assigned to this ancestry, otherwise the individual was assigned to admix ancestry as in the 1M veteran cohort.⁵³ According to this criterion there are 1818 individuals from European ancestry (EUR), 190 from African ancestry (AFR), 158 from East Asian ancestry (EAS), 254 from South Asian ancestry (SAS), and 301 individuals with admixed ancestry (2 or more).

Imputation

Genotype files were converted to plus strand and SNPs with Hardy-Weinberg Equilibrium (HWE) p-value<10⁻⁶ were removed. Imputation was calculated using the TOPMed reference panel,⁵⁷ and results were given in GRCh38 human reference genome and plus strand. The imputed dataset was filtered for monogenic and low imputation quality score (r^2 <0.4) using BCFTools 1.9. To perform GWAS, files in VCF format were further filtered for r^2 >0.9 and converted to BGEM format using QCtools 1.3.⁵⁸

UK Biobank imputed variants with imputation score >0.9 and overlapping our set of variants (n=5,981,137) were extracted and merged with GenOMICC data into a single BGEM file containing cases and controls using QCtools 1.3.

GWAS

Related individuals to degree 3 were removed. 13 individuals with American ancestry were removed as the sample size provided insufficient power to perform a reliable GWAS for this group. The final dataset includes 2244 individuals. Using PCA to infer genetic ancestry, there were 1676 individuals from European ancestry, 149 individuals from East Asian ancestry, 237 individuals from South Asian ancestry and 182 individuals from African ancestry (Extended Data Table 1). If age or deprivation status were missing for some individuals, the value was set to the mean of their ancestry. GWAS were performed separately for each ancestry group.

Tests for association between case-control status and allele dosage at individuals SNPs were performed by fitting logistic regression models using PLINK.⁵⁹ Independent analyses were performed for each ethnic group. All models included sex, age, mean-centered age², deprivation score decile of residential postcode, and the first 10 genomic principal components as covariates.

Article

Genomic principal components were computed on the combined sample of all UK Biobank and GenOMICC participants. Specifically, 456,750 genetic variants were identified which were shared between the variants contained in the called genotypes in the GenOMICC dataset and imputed UK Biobank genotypes, which had an imputation info score above 0.95 and a minor allele frequency above 1%. After merging genotypes at these variants, variants were removed which had a minor allele frequency below 2.5%, a missingness rate above 1.5%, showed departure from Hardy-Weinberg equilibrium with a p value below 10^{-50} , or which were within previously identified regions of high linkage disequilibrium within UK Biobank. After LD-pruning of the remaining variants to a maximum r^2 of 0.01 based on a 1000 variant window moving in 50 variants steps, using the PLINK indep-pairwise command and yielding 13,782 SNPs, the leading 20 genomic principal components were computed using FlashPCA2.⁶⁰

GWAS results for European ancestry were filtered for MAF>0.01, HWE p-value $> 10^{-50}$ and genotyping rate > 0.99 . An extra filter was added to avoid bias for using a different genotyping method and imputation panel between controls and cases. This could not be controlled for using regression because all cases and all controls were genotyped using different methods. MAF for each ancestry were compared between UK Biobank European controls and gnomAD hg38 non-Finnish Europeans downloaded in August 2020.⁶¹ SNPs were removed from the GWAS results following these two rules: (a) In SNPs with MAF > 10% in gnomAD, an absolute difference of 5% between gnomAD and UK biobank controls MAF (b) In SNPs with MAF < 10% in gnomAD, a difference > 25% gnomAD MAF, between UK Biobank controls and gnomAD. GWAS from non-European ancestries were filtered for a MAF in UK Biobank controls corresponding to the same ancestry > 5% and then for the SNPs that passed QC in the European GWAS. To calculate differences between UK Biobank European individuals and gnomAD allele frequencies, non Finnish-Europeans gnomAD allele frequencies were used, as European UK Biobank controls are mainly non-Finnish.

Filtered GWAS for each ancestry, containing a total of ~4.7M SNPs, were combined in a trans-ethnic meta-analysis using METAL⁶² standard error mode and controlling for population stratification (genomic control on). Nearest genes were defined using FUMA v1.3.6 SNP2GENE function,⁶³ using LDR²>0.6 and UK Biobank release 2 reference panel.

A sex-specific GWAS within European individuals was performed using 1180 unrelated male cases and 496 unrelated female cases and 5 UK Biobank random controls matched by sex and ancestry for each case. Test for association between case-control status and allele dosage at individual SNPs were performed by fitting a logistic regression model with PLINK. Age, mean age squared, deprivation decile of residential postcode and the first 10 principal components were added as covariates in the models.

Deprivation score. The UK Data Service provides measures of deprivation based on Census Data and generated per postcode. The latest version of the Deprivation Scores were published in 2017 and are based on the 2011 census. Since only partial postcodes were available for most samples we were unable to use these indices directly. However, we generated an approximation to the scores by calculating an average weighted by population count across the top-level postcode areas.

The initial input file was part of the aggregated census data identified by <https://doi.org/10.5257/census/aggregate-2011-2>.

Specifically the postcode data were downloaded from: http://s3-eu-west-1.amazonaws.com/statistics.digitalresources.jisc.ac.uk/dkan/files/Postcode_Counts_and_Deprivation_Ranks/postcodes.zip.

Population count and deprivation score for each published postcode were extracted and weighted average score calculated for each top-level postcode. We further categorised each top-level postcode score into decile and quintile bins for more coarse-grained analyses.

Whole Genome Sequencing. Whole Genome Sequencing (WGS) gVCF files were obtained for the 1667 individuals for which we had whole genome sequence data. Variants overlapping the positions of the imputed variants were called using GATK and variants with depth<8X (the minimum depth for which 95% coverage can be expected) were filtered. Individual VCF files were joined in a multi-sample VCF file for comparison with imputed variants. 1613 of these 1667 were used in the final GWAS. Samples were filtered and variants annotated using bcftools 1.9. VCF files obtained from imputation were processed in an identical manner. Alternative allele frequency was calculated with PLINK 2.0⁶⁴ for both WGS and imputed data.

Controls

UK Biobank. UK Biobank participants were considered as potential controls if they were not identified by the UK Biobank as outliers based on either genotyping missingness rate or heterogeneity, and their sex inferred from the genotypes matched their self-reported sex. For these individuals, information on sex (UKBID 31), age, ancestry, and residential postcode deprivation score decile was computed. Specifically, age was computed as age on April 1st, 2020 based on the participant's birth month (UKBID 34) and year (UKBID 52). The first part of the residential postcode of participants was computed based on the participant's home location (UKBID 22702 and 22704) and mapped to a deprivation score decile as previously described for GenOMICC participants. Ancestry was inferred as previously described for GenOMICC participants.

After excluding participants who had received PCR tests for Covid-19, based on information downloaded from the UK Biobank in August 2020, five individuals with matching inferred ancestry were sampled for each GenOMICC participant as controls. After sampling each control, individuals related up to 3rd degree were removed from the pool of potential further controls. An additional analysis with more stringent matching on individual characteristics was also performed (Supplementary Information: Matched controls).

The 100,000 Genomes Project. Following ethical approval (14/EE/1112 and 13/EE/032), consenting participants from the 100,000 Genomes Project with a broad range of rare diseases, cancers and infection were enrolled by 13 regional NHS Genomic Medicine Centres across England and in Northern Ireland, Scotland and Wales and whole blood was drawn for DNA extraction. After quality assurance whole genome sequencing at 125 or 150 base pairs was performed by Illumina Laboratory Services on either Hiseq 2500 or Hiseq X sequencers in the Genomics England Sequencing Centre, followed by detection of small variants (single nucleotide variants and small indels) using Starling.

Test for association between cases-control status were performed by running mixed model association tests using SAIGE (v0.39). 1675 individuals from the GenOMICC study and 45,875 unrelated participants and of European ancestry were included. Genomic principal components were calculated for the combined dataset of GenOMICC participants and whole genome sequence data from the 100,000 Genomes Project. Principal Components Analysis (PCA) was performed with GCTA software using approximately 30,000 SNPs selected with minor allele frequency >0.005 and after LD pruning ($r^2 < 0.1$ with a window size of 500kb). Fitting of the null logistic mixed model was performed using the SNPs used for PCA and included age, sex, squared age, age \times sex and first 20 genomic principal components as covariates.

Test for association using SAIGE was performed after filtering of variants in the WGS dataset for genotype quality and minor allele frequency ≥ 0.05 . GWAS-specific quality filtering was performed to include variants with minor allele count ≥ 20 for each phenotype, differential missingness between cases and controls (p-value $< 1 \times 10^{-5}$) and departure from Hardy-Weinberg equilibrium (p-value $< 1 \times 10^{-5}$).

Generation Scotland. Generation Scotland: Scottish Family Health Study (hereafter referred to as Generation Scotland) is a population-based cohort of 24 084 participants sampled from five regional centers across Scotland(**Error! Hyperlink reference not valid.**).⁶⁵ A large subset of participants were genotyped using either Illumina HumanOmniExpressExome-8v1_A or v1-2, and 20 032 passed QC criteria previously described.^{66,67} Genotype imputation using the TOPMed reference panel was recently performed (freeze 5b) using Minimac4 v1.0 on the University of Michigan server <https://imputationserver.sph.umich.edu>.⁶⁸ Imputation data from 7689 unrelated (genomic sharing identical by descent estimated using PLINK1.9 < 5%) participants were used as control genotypes in a GWAS using GenOMICC cases of European ancestry, for quality check purpose of associated variants. GWAS was performed in a logistic regression framework implemented in the PLINK2 (<https://www.cog-genomics.org/plink/2.0/>) glm function, adjusting for age, sex and the first 10 principal components of European ancestry. These coordinates were obtained from projection to the principal components space of 1000 Genomes European population samples using KING v2.2.5³⁴ and a LD-pruned subset of target genotyped markers passing quality check and intersecting with the reference populations.

Validation. Clumped hits in discovery GWAS were validated using controls from Generation Scotland and 100K. To consider a hit validated, the direction of effect should be the same in all three GWAS and the p-value in both Generation Scotland and 100K had to be $p < 0.05/n_{\text{validations}}$, where $n_{\text{validations}}$ is the number of significant independent loci in our analysis at the discovery threshold of $p < 5 \times 10^{-8}$.

Replication

GenOMICC EUR loci were defined using the clump function of PLINK 1.9⁶⁴ and clumping parameters $r^2 = 0.1$, $p_{\text{val}} = 5 \times 10^{-8}$ and $p_{\text{val},2} = 0.01$; distance to the nearest gene was calculated using ENSEMBL GRCh37 gene annotation.

No GWAS has been reported of critical illness or mortality in Covid-19. As a surrogate, to provide some replication for our findings, replication analyses were performed using Host Genetics Initiative build 37, version 2 (July 2020) B2 (hospitalised Covid-19 vs population) GWAS. Summary statistics were used from the full analysis, including all cohorts and GWAS without UK Biobank, to avoid sample overlap. Replication p-value was set to 6.25×10^{-4} ($0.05/8$, where 8 is the number of loci significant in the discovery).

Genome-wide meta-analysis

Meta-analysis between GenOMICC, HGI and 23andMe was performed using fixed-effect inverse variance meta-analysis in METAL,⁶² with correction for genomic control on. The 23andMe study comprises cases and controls from EUR genetic ancestry group. The HGI B2 analysis is a trans-ancestry meta-analysis, with the great majority of cases being multi-ethnic European (EUR and FIN), with 238 cases of non-European ancestry (176 Admixed American, AMR, from BRACOVID study and 62 South Asian, SAS, from the GNH study).

Post-GWAS analyses

TWAS and Meta-TWAS. We performed transcriptome-wide association using the MetaXcan framework²³ and the GTEx v8 eQTL MASHR-M models available for download (<http://predictdb.org/>). To increase SNP coverage to perform TWAS, first GWAS summary statistics for European ancestry were imputed using the fizi⁶⁹ impute function (<https://github.com/bogdanlab/fizi>), 1000 genomes European population as LD reference and 30% as minimum proportion of SNPs for a region (-min-prop 0.3). Then, imputed GWAS results were harmonised, lifted over to hg38 and linked to 1000 Genomes reference panel using GWAS tools <https://github.com/hakyimlab/summary-gwas-imputation/wiki/GWAS-Harmonization-And-Imputation>.

Imputed and harmonised GWAS summary statistics were used to perform TWAS for whole blood (Supplementary Figure 16) and lung (Figure 2) GTEx v8 tissues with S-PrediXcan function. Resulting p-values were corrected using the Bonferroni correction to find significant gene associations. To overcome the limitations of sample size in GTEx v8 lung and whole blood tissues, we performed a meta-twas prioritising genes with small p-values in these tissues and using GTEx v8 gene expression in all tissues and S-Multixcan.⁷⁰

Mendelian randomisation. Two-sample summary data based Mendelian randomisation¹⁹ was performed using the results of GenOMICC and the Genotype-Tissue expression project,⁷¹ GTEx v7 (using SMR/HEIDI pre-prepared data: <https://cnsgenomics.com/software/smr/#DataResource>), with Generation Scotland^{65,72} forming a linkage disequilibrium reference. GenOMICC results from those of European ancestry were used as the outcome; and GTEx (v7) whole blood expression results as the exposure. Additional data pertaining to GTEx v7 were downloaded from GTEx: <https://gtexportal.org/> (accessed 20 Feb 2020, 05 Apr 2020, and 04 Jul 2020), and SMR/HEIDI from <https://cnsgenomics.com/software/smr/> (accessed 03 Jul 2020). Analyses were conducted using Python 3.7.3 and SMR/HEIDI v1.03 (plots were made using SMR/HEIDI v0.711). An LD reference was created using data from the population-based Generation Scotland cohort (used with permission; described previously⁶⁷): from a random set of 5,000 individuals, using Plink v1.9 (www.cog-genomics.org/plink/1.9/), a set of individuals with a genomic relatedness cutoff < 0.01 was extracted; 2,778 individuals remained in the final set. All data used for the SMR/HEIDI analyses were limited to autosomal biallelic SNPs: 4,264,462 variants remained in the final merged dataset.

Significant (as per GTEx v7; nominal p-value below nominal p-value threshold) local (distance to transcriptional start site $< 1\text{Mb}$) eQTL from GTEx v7 whole blood for protein coding genes (as per GENCODE v19) with a MAF > 0.01 (GTEx v7 and GenOMICC) were considered as potential instrumental variables. Per variant, we first selected the Ensembl gene ID to which it was most strongly associated followed by selecting the variant to which each Ensembl gene ID was most strongly associated. Instruments were available for 4,614 unique Ensembl gene IDs.

Results were assessed based upon a list of genes selected *a priori* as of interest (Supplementary Table 3), and together as a whole. Replication of Bonferroni-corrected significant results was attempted in the results of Covid-19-Host Genetics Initiative - <https://www.covid19hg.org/> - with UK Biobank excluded (July 2nd 2020 data release) using the eQTLgen expression dataset.²⁰ Hospitalized Covid-19 vs. population (ANA_B2_V2) was selected as the phenotype most similar to our own, and therefore the most appropriate for use as a replication cohort.

In order to further validate the analyses above, generalized summary-data Mendelian randomization (GSMR)⁷³ was performed using exposure data from <https://www.eqtlgen.org/index.html> (accessed 26/10/2020)²⁰ and the publicly available GenOMICC EUR data for TYK2 and IFNAR2 (Supplementary Figure 15). GSMD was performed using GCTA version 1.92.1 beta6 Linux. Pleiotropic SNPs were filtered using HEIDI-outlier test (threshold = 0.01) and instrument SNPs were selected at a genome-wide significance level ($P_{\text{eQTL}} < 5e-8$) using LD clumping (LD r^2 threshold = 0.05 and window size = 1Mb). The imputed genotypes for 50,000 unrelated individuals (based on SNP-derived genomic relatedness < 0.05 using HapMap 3 SNPs) from the UK Biobank were used as the LD reference for clumping. GSMD accounts for remaining LD not removed by LD clumping.

Genomic region plots. Genomic region plots were created using <https://github.com/Geeketics/LocusZooms> (Supplementary Figures 5,6).

Gene-level and pathway analyses. Gene-level burden of significance in the EUR ancestry group result was calculated using MAGMA v1.08 (Supplementary Figure 17).⁷⁴ SNPs were annotated to genes by mapping

Article

based on genomic location. SNPs were assigned to a gene if the SNPs location is within 5 kb up- or down-stream of the gene region (defined as the transcription start site to transcription stop site). The MAGMA SNP-wise mean method was applied which utilises the sum of squared SNP Z-statistics as the test statistic. The 1000 Genomes Project European reference panel was used to estimate LD between SNPs.

Auxiliary files were downloaded from <https://ctg.cncr.nl/software/magma> on 1st September 2020. Gene location files for protein-coding genes were obtained from NCBI (<ftp.ncbi.nlm.nih.gov>):

gene/DATA/GENE_INFO/Mammalia/Homo_sapiens.gene_info.gz
on 29/04/2015, and from:
genomes/Homo_sapiens/ARCHIVE/ANNOTATION_RELEASE.105/
mapview/seq_gene.md.gz
on 25/05/2016.

The reference data files used to estimate LD are derived from Phase 3 of the 1000 Genomes Project.

Competitive gene set enrichment analysis was conducted in MAGMA using a regression model that accounts for gene-gene correlations, to reduce bias resulting from clustering of functionally similar genes on the genome.⁷⁴ Gene sets were queried from the databases KEGG 2019, Reactome 2016, GO Biological Process 2018, Biocarta 2016 and WikiPathways 2019. The Benjamini-Hochberg procedure was used to control false discovery rate (<0.05).

Meta-analysis by information content. In order to put these results in the context of existing biological data about host genes in SARS-CoV-2 replication and response, we performed meta-analysis of information content (MAIC)²⁴ analysis integrating gene-level results from GenOMICC metaTWAS with an existing systematic review of host factors implicated in SARS-CoV-2 viral replication and host response in Covid-19.⁴⁵

We developed meta-analysis by information content (MAIC) to evaluate and integrate gene-level data from diverse sources.²⁴ Multiple *in vitro* and *in vivo* studies have identified key host genes that either directly interact with SARS-CoV-2, or define the host response to SARS-CoV-2. We have previously conducted a systematic review of these studies.⁴⁵ In order to put the new associations from this GWAS into context, we performed a data-driven meta-analysis of gene-level results combined with pre-existing biological data using meta-analysis by information content (MAIC).²⁴

Briefly, MAIC aggregates both ranked and unranked lists and performs better than other methods, particularly when presented with heterogeneous source data. The input to MAIC is a list of named genes. MAIC assigns a *score* to each gene according to how many source datasets have reported that gene, and then creates a data-driven *weighting* for each data source (usually an individual experiment) based on the scores of the genes that are highly-ranked on that list. This procedure is performed iteratively until the scores and weightings converge on stable values. In order to prevent a single type of experiment from unduly biasing the results, input gene lists are assigned to categories, and a rule applied that only one weighting from each category can contribute to the score for any given gene.

Tissue/functional genomic enrichment. We downloaded the mean gene expression data summarised from RNA sequencing by the GTEx project (<https://gtexportal.org/>). The GTEx v7 data contain gene expressions of 19,791 genes in 48 human tissues. Gene expression values were normalized to numbers of transcripts per million reads (TPM). To measure the expression specificity of each gene in each tissue, each gene expression specificity was defined as the proportion of its expression in each tissue among all the tissues, i.e., a value ranging between 0 and 1. SNPs within the 10% most specifically expressed genes in each tissue were annotated for subsequent testing of heritability enrichment. For functional genomic enrichment analysis, we considered the inbuilt primary functional annotations v2.2 provided in the ldsc software (<https://alkesgroup.broadinstitute.org/LDSCORE/>) to annotated the SNPs.

With the annotated SNPs, we used stratified LD score regression (S-LDSC)⁷⁵ to test whether any human tissue or specific functional genomic feature is associated with severe Covid-19. Our GWAS summary statistics were harmonized by the munge_sumstats.py procedure in ldsc. LD scores of HapMap3 SNPs (MHC region excluded) for gene annotations in each tissue were computed using a 1-cM window. The enrichment score was defined as the proportion of heritability captured by the annotated SNPs divided by the proportion of SNPs annotated.

Genetic correlations. We applied both the LD score regression (LDSC)⁷⁶ and high-definition likelihood (HDL)²⁵ methods to evaluate the genetic correlations between Severe Covid-19 and 818 GWASed phenotypes stored on LD-Hub.⁷⁷ GWAS summary statistics were harmonized by the munge_sumstats.py procedure in the ldsc software. In the HDL analysis, we estimated the SNP-based narrow-sense heritability for each phenotype, and for the 818 complex traits GWASs, those with SNPs less than 90% overlap with the HDL reference panel were removed.

Genome build. Results are presented using Genome Reference Consortium Human Build 37. Imputed genotypes and whole-genome sequence data were lifted over from Genome Reference Consortium Human Build 38 using Picard liftoverVCF mode from GATK 4.0 which is based on the UCSC liftover tool (chain file obtained from ftp://ftp.ensembl.org/pub/assembly_mapping/homo_sapiens/GRCh38_to_GRCh37.chain.gz).⁷⁸

Reporting summary

Further information on research design is available in the Nature Research Reporting Summary linked to this paper.

Data availability

Full summary-level data in support of the findings of this study are available from <https://genomicc.org/data>. Individual level data can be analysed by qualified researchers in the ISARIC4C/GenOMICC data analysis platform by application at <https://genomicc.org/data>. The full GWAS summary statistics for the 23andMe discovery dataset are available through 23andMe to qualified researchers under an agreement with 23andMe that protects the privacy of the 23andMe participants. Please visit <https://research.23andMe.com/dataset-access/> for more information and to apply to access the data.

Acknowledgements We thank the patients and their loved ones who volunteered to contribute to this study at one of the most difficult times in their lives, and the research staff in every intensive care unit who recruited patients at personal risk during the most extreme conditions we have ever witnessed in UK hospitals. GenOMICC was funded by Sepsis Research (the Fiona Elizabeth Agnew Trust), the Intensive Care Society, a Wellcome-Beit Prize award to J. K. Baillie (Wellcome Trust 103258/Z/13/A) and a BBSRC Institute Program Support Grant to the Roslin Institute (BBS/E/D/20002172, BBS/E/D/20002070 and BBS/E/D/30002275). Whole-genome sequencing was done in partnership with Genomics England and was funded by UK Department of Health and Social Care, UKRI and LifeArc. ISARIC4C is supported by grants from: the Medical Research Council [grant MC_PC_19059], the National Institute for Health Research (NIHR) [award CO-CIN-01] and by the NIHR Health Protection Research Unit (HPRU) in Emerging and Zoonotic Infections at University of Liverpool in partnership with Public Health England (PHE), in collaboration with Liverpool School of Tropical Medicine and the University of Oxford [award 200907], NIHR HPRU in Respiratory Infections at Imperial College London with PHE [award 200927], Wellcome Trust and Department for International Development [215091/Z/18/Z], and the Bill and Melinda Gates Foundation [OPPI1209135], and Liverpool Experimental Cancer Medicine Centre (Grant Reference: C18616/A25153), NIHR Biomedical Research Centre at Imperial College London [IS-BRC-1215-20013], EU Platform foR European Preparedness Against (Re-) emerging Epidemics (PREPARE) [FP7 project 602525] and NIHR Clinical Research Network for providing infrastructure support for this research. PJMO is supported by a NIHR Senior Investigator Award [award 2021385]. The views expressed are those of the authors and not necessarily those of the DHSC, DID, NIHR, MRC, Wellcome Trust or PHE. HM was supported by the NIHR BRC at University College London Hospitals. The Health Research Board of Ireland (Clinical Trial Network Award 2014-12) funds collection of samples in Ireland. This research has been conducted using the UK Biobank Resource under project 788. Generation Scotland received core support from the Chief Scientist Office of the Scottish Government Health Directorates [CZD/16/6] and the Scottish Funding Council [HR03006] and is currently supported by the Wellcome Trust [216767/Z/19/Z]. Genotyping of the GS:sFHS samples was carried out by the Genetics Core Laboratory at the Edinburgh Clinical Research Facility, University of Edinburgh, Scotland and was funded by the Medical Research Council UK and the Wellcome Trust (Wellcome Trust Strategic Award Stratifying Resilience and Depression Longitudinally (STRADL) Reference 104036/Z/14/Z). Genomics England and the 100,000 Genomes Project was funded by the National Institute for Health Research, the Wellcome Trust, the Medical Research Council, Cancer Research UK, the Department of Health and Social Care and NHS England. M Caulfield is an NIHR Senior Investigator. This work is part of the portfolio of translational research at the NIHR Biomedical Research Centre at Barts and Cambridge. Research performed at the Human Genetics Unit was funded by the MRC (MC_UU_00007/10, MC_UU_00007/15). LK was supported by an RCUK Innovation Fellowship from the National Productivity Investment Fund (MR/R026408/1). A Bretherick acknowledges funding from the Wellcome Trust PhD training fellowship for clinicians (204979/Z/16/Z), and the Edinburgh Clinical Academic Track (ECAT) programme. We acknowledge support from the MRC Human Genetics Unit programme grant, "Quantitative traits in health and disease" (U. MC_UU_00007/10). A. Tenesa acknowledges funding from MRC research grant MR/P015514/1, and HDR-UK award HDR-9004 and HDR-9003. This study owes a great deal to the National Institute of Healthcare Research Clinical Research Network (NIHR CRN) and the Chief Scientist Office (Scotland), who facilitate recruitment into research studies in NHS hospitals, and to the global ISARIC and InFACT consortia. The authors wish to thank Dr Rebecca Coll, Wellcome-Wolfson Institute, Queen's University Belfast, for advice on interpretation of these results, and Dr. Jie Zheng (University of Bristol) for sharing the harmonized GWAS summary statistics used in LD-Hub. The authors wish to express their gratitude to the anonymous peer reviewers for a number of substantive improvements to the manuscript and analysis. The views expressed here are purely those of the authors and may not in any circumstances be regarded as stating an official position of the European Commission.

Article

Author contributions JK, PK, CHi, PH, AN, DM, LL, DMC, HM, TW, CPP and JKB contributed to study design. SC, JF, FG, WO, SK, AF, KR, LM, PJO, MGS, AL and JKB contributed to study coordination. NW, AF and LM contributed to laboratory work. EP-C, SC, LK, ADB, KR, DP, SW, NP, MHF, JF, AR, EG, DH, BW, YW, AM, AK, LM, ZY, RZ, CZ, GG, BS, MZ, CH, JY, XS, CPP, AT, KR, AL, VV, JFW and JKB contributed to data analysis. SC, CDR, DJP, CHa, CS, MS-H, LT, AH, SCM, AP, ARe, MC, RS and JKB contributed to recruitment of cases and controls. SC, CDR, RB, JM and JKB contributed to interpretation of findings. EP-C, SC, LK, ADB, KR, CDR, RB, JM, CPP, KR, JFW and JKB contributed to manuscript preparation. JKB conceived the study and wrote the first draft of the manuscript. All authors approved the final version of the manuscript. GenOMICC Recruiting sites are listed below in descending order of the number of patients recruited per site.

Competing interests The authors declare no competing interests.

Correspondence and requests for materials should be addressed to J.K.B.

Peer review information *Nature* thanks Paul McLaren and the other, anonymous, reviewer(s) for their contribution to the peer review of this work. Peer reviewer reports are available.

Reprints and permissions information is available at <http://www.nature.com/reprints>.

ACCELERATED ARTICLE PREVIEW

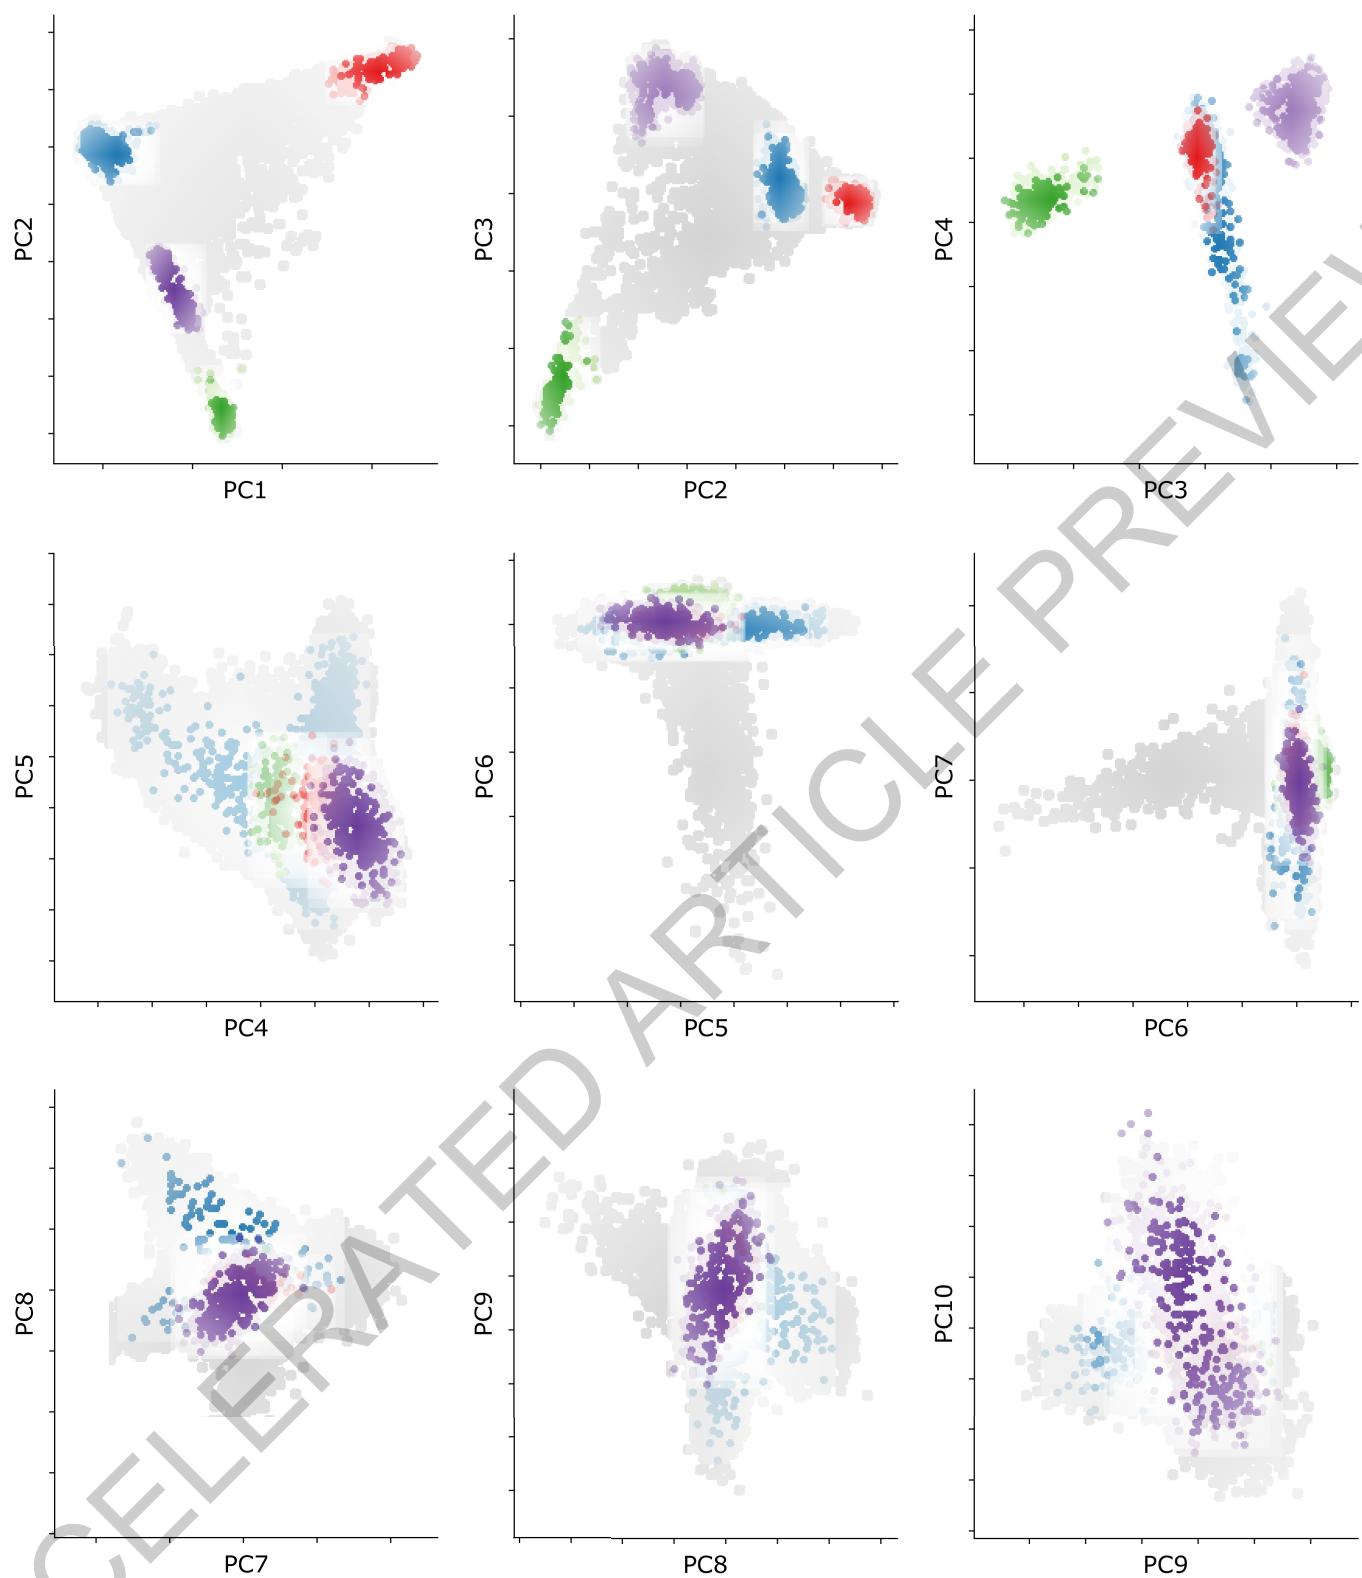

Extended Data Fig. 1|Q:Q plots. Raw (uncorrected) p-values are shown for each ancestry group in GenOMICC: gcc.eur - European; gcc.afr - African; gcc.eas - East Asian; gcc.sas - South Asian, together with trans-ethnic meta-analysis (gcc.te.meta), and meta-analysis comprising GenOMICC, HGI and 23andMe

data (gcc.hgi.23m). λ - genomic inflation value. Note that some residual inflation is evident in the primary analysis in GenOMICC EUR. Repeating the analysis using more principal components (20PCs) as covariates did not improve the inflation ($\lambda_{0.5} = 1.10$).

Extended Data Fig. 2 | MAIC shared information content. Representation of shared information content among data sources in MAIC analysis. Each experiment or data source is represented by a block on the outer ring of the circle; size of data source blocks is proportional to the summed information content of input list: i.e. the total contribution that this data source makes to the aggregate, calculated as the sum of the MAIC gene scores contributed by that list. Lines are colored according to the dominant data source. Data sources within the same category share the same color (see legend). The largest categories and data sources are labelled: Sun_2020,⁷⁹ rosa_2020,⁸⁰

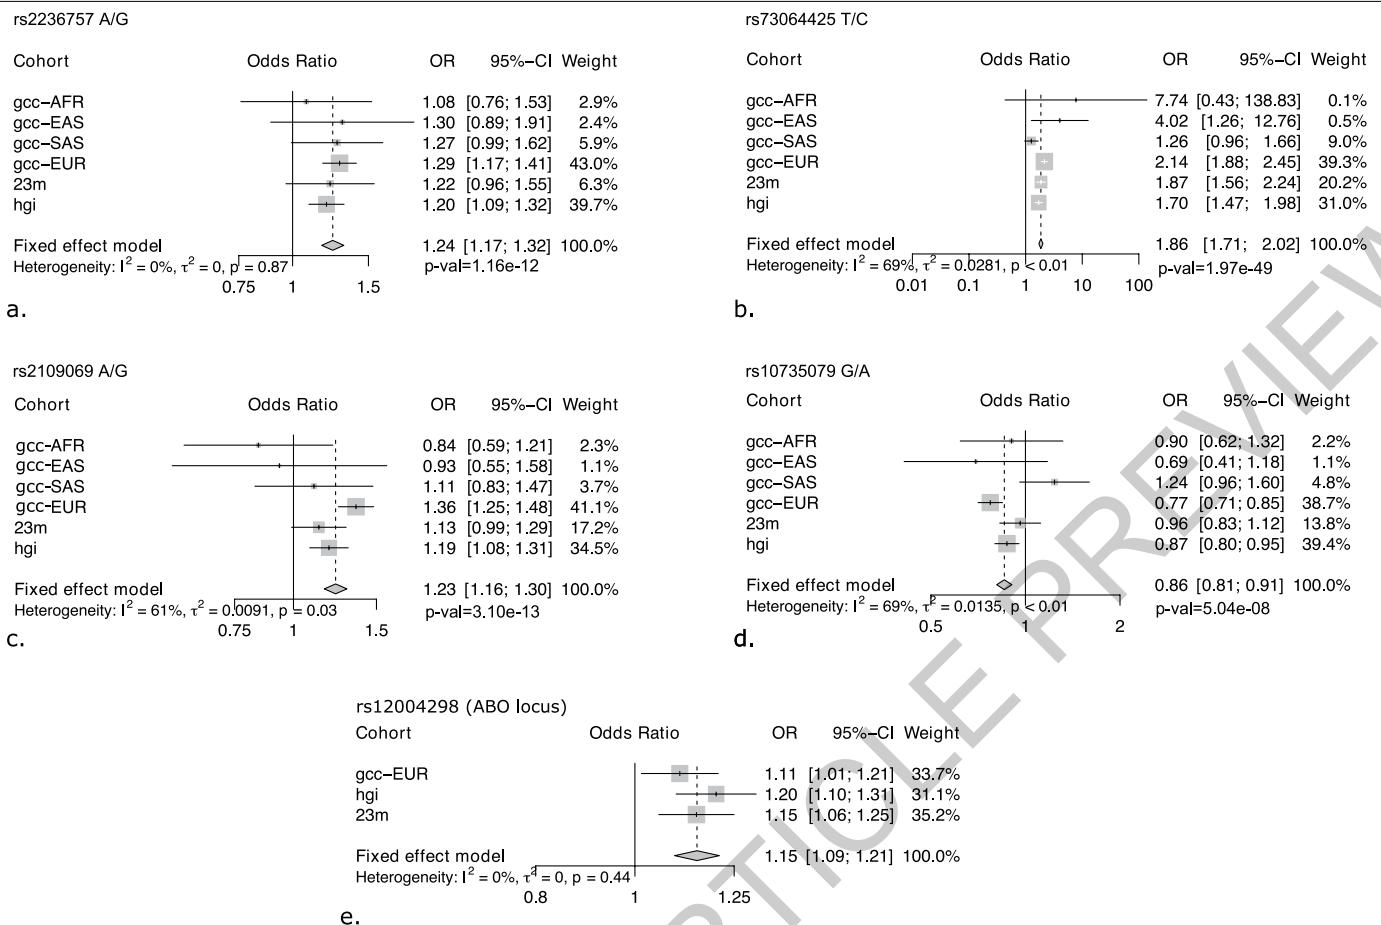

zhang_2020,⁸¹ langelier_2020,⁸² wei_2020,⁸³ heaton_2020.⁸⁴ An interactive version of this figure is available at <https://baillielab.net/maic/covid>. In order to estimate the probability of the specific enrichment for GenOMICC metaTWAS, we randomly sampled from the baseline distribution of metaTWAS genes 1000 times, re-running MAIC with the same set of Covid-19 systematic review inputs, but substituting the randomly sampled input list for the GenOMICC metaTWAS results. Modeling a normal distribution based on these empirical results, we estimated the probability of a MAIC enrichment this strong arising by random chance at $p = 4.2 \times 10^{-12}$.

Extended Data Fig. 3 | Genomic overlap among cases and controls. PCA plots showing the distribution of all cases and controls for the first 10 principal components. Cases are shown as coloured closed circles: European (EUR, blue), African (AFR, red), East Asian (EAS, green), and South Asian (SAS, purple).

Controls for each ancestry group are shown as closed circles in a lighter shade of the colour for that ancestry group. UK Biobank population background is shown as light grey closed circles.

Article

Extended Data Fig. 4 | Effect sizes in ancestry groups within the GenOMICC study. Data are shown for the four replicated variants with genome-wide significant association in GenOMICC (a-d), and the ABO locus(e). Forest plots display effect size heterogeneity measures and p-value (p) and meta-analysis estimates with 95% confidence interval, and p-value (P-val) under a fixed effect model. Allele in bold is the reference allele for the reported effect (odds ratio). Sample sizes for the cases+controls analysed in the four groups were: 1092 for

African (AFR), 894 for East Asian, 10055 for European and 1422 for south Asian (SAS) cases within GenOMICC. HGI - Covid-19 Host Genetics Initiative; 23m - 23andMe. Observed heterogeneity in effect size may be due to genuine differences between ancestry groups, or due to the limited statistical power in smaller groups (evident from the broad confidence intervals), or due to residual confounding.

Extended Data Table 1 | Baseline characteristics of 2244 patients included

Patient Characteristics	GenOMICC (n=2109)	ISARIC 4C (n=135)
		<i>missing data</i>
Female sex	624 (30%)	46 (34%)
Age (yrs, mean \pm SD)	57.3 \pm 12.1	57.3 \pm 2.9
European ancestry	1573 (75%)	103 (76%)
South Asian ancestry	219 (10%)	18 (13%)
African ancestry	174 (8%)	8 (6%)
East Asian ancestry	143 (7%)	6 (4%)
Significant comorbidity	396 (19%)	40 (30%)
Invasive ventilation	1557 (74%)	25 (19%)
Died (60 days)	459 (22%)	22 (16%)
		<i>missing data</i>

Ancestry groups were determined by principal components analysis (Extended Data Figure 3). Significant comorbidity was defined as the presence of functionally limiting comorbid illness in GenOMICC, in the assessment of the treating clinicians. In ISARIC4C significant comorbidity refers to the presence of any chronic cardiac, lung, kidney, or liver disease, cancer or dementia. Age is shown as mean \pm standard deviation.

Article

Extended Data Table 2 | Replication in external data

SNP	chr:pos(b37)	Risk	Alt	OR _{gcc.ukb}	P _{gcc.ukb}	OR _{hgi.23m}	P _{hgi.23m}	Locus
rs73064425	3:45901089	T	C	2.1	4.8 x 10 ⁻³⁰	1.7	1.5 x 10 ^{-28*}	<i>LZTFL1</i>
rs9380142	6:29798794	A	G	1.3	3.2 x 10 ⁻⁸	1	0.76	<i>HLA-G</i>
rs143334143	6:31121426	A	G	1.9	8.8 x 10 ⁻¹⁸	1.1	0.019	<i>CCHCR1</i>
rs3131294	6:32180146	G	A	1.5	2.8 x 10 ⁻⁸	0.99	0.91	<i>NOTCH4</i>
rs10735079	12:113380008	A	G	1.3	1.6 x 10 ⁻⁸	1.1	0.00082*	<i>OAS1/3</i>
rs2109069	19:4719443	A	G	1.4	4 x 10 ⁻¹²	1.1	5 x 10 ^{-5*}	<i>DPP9</i>
rs74956615	19:10427721	A	T	1.6	2.3 x 10 ⁻⁸	1.4	2 x 10 ^{-6*}	<i>TYK2</i>
rs2236757	21:34624917	A	G	1.3	5 x 10 ⁻⁸	1.2	4.1 x 10 ^{-5*}	<i>IFNAR2</i>

Risk – risk allele; Alt - alternative allele; OR - effect size (odds ratio) of the risk allele; CI - 95% confidence interval for the odds ratio; P - p-value, locus – gene nearest to the top SNP. Subscript identifiers show the data source: gcc - GenOMICC study, European ancestry, comparison with UK Biobank; hgi.23m - Covid-19 Host Genetics Initiative and 23andMe meta-analysis, used for replication. * Bonferroni significant values are highlighted and indicate external replication.

Reporting Summary

Nature Research wishes to improve the reproducibility of the work that we publish. This form provides structure for consistency and transparency in reporting. For further information on Nature Research policies, see our [Editorial Policies](#) and the [Editorial Policy Checklist](#).

Statistics

For all statistical analyses, confirm that the following items are present in the figure legend, table legend, main text, or Methods section.

n/a Confirmed

- The exact sample size (n) for each experimental group/condition, given as a discrete number and unit of measurement
- A statement on whether measurements were taken from distinct samples or whether the same sample was measured repeatedly
- The statistical test(s) used AND whether they are one- or two-sided
 - Only common tests should be described solely by name; describe more complex techniques in the Methods section.*
- A description of all covariates tested
- A description of any assumptions or corrections, such as tests of normality and adjustment for multiple comparisons
- A full description of the statistical parameters including central tendency (e.g. means) or other basic estimates (e.g. regression coefficient) AND variation (e.g. standard deviation) or associated estimates of uncertainty (e.g. confidence intervals)
- For null hypothesis testing, the test statistic (e.g. F , t , r) with confidence intervals, effect sizes, degrees of freedom and P value noted
 - Give P values as exact values whenever suitable.*
- For Bayesian analysis, information on the choice of priors and Markov chain Monte Carlo settings
- For hierarchical and complex designs, identification of the appropriate level for tests and full reporting of outcomes
- Estimates of effect sizes (e.g. Cohen's d , Pearson's r), indicating how they were calculated

Our web collection on [statistics for biologists](#) contains articles on many of the points above.

Software and code

Policy information about [availability of computer code](#)

Data collection	Illumina i-scan platform, GenomeStudio Analysis software v2.0.3, GSAMD-24v3-0-EA_20034606_A1.bpm manifest and cluster file provided by manufacturer
Data analysis	GenomeStudio v2.03, DRAGEN v0.1.11.269.3.2.22, GATK 4.1.8.1, Plink 1.9, Plink 2.0, King 2.1, R v3.6, python v3.7, GATK 4.0, USC liftover, GCTA v1.92 ,SAIGE v0.39, metal, MAGMAv1.08, BCFTools 1.9, QCtools 1.3, FlashPCA2, admixture, FUMA v1.3.6, SMR/HEIDI v1.03, MetaXcan (git commit 0b7c10d633d3d7bfe794e4f35bd8190356bb2514), MiniMac4 v1.0,

For manuscripts utilizing custom algorithms or software that are central to the research but not yet described in published literature, software must be made available to editors and reviewers. We strongly encourage code deposition in a community repository (e.g. GitHub). See the Nature Research [guidelines for submitting code & software](#) for further information.

Data

Policy information about [availability of data](#)

All manuscripts must include a [data availability statement](#). This statement should provide the following information, where applicable:

- Accession codes, unique identifiers, or web links for publicly available datasets
- A list of figures that have associated raw data
- A description of any restrictions on data availability

Full summary-level data in support of the findings of this study are available for download from [<https://genomicc.org/data>]. Individual level data can be analysed by qualified researchers in the ISARIC 4C/GenOMICC data analysis platform by application at [<https://genomicc.org/data>].

The full GWAS summary statistics for the 23andMe discovery data set will be made available through 23andMe to qualified researchers under an agreement with

23andMe that protects the privacy of the 23andMe participants. Please visit <https://research.23andMe.com/dataset-access/> for more information and to apply to access the data.

Field-specific reporting

Please select the one below that is the best fit for your research. If you are not sure, read the appropriate sections before making your selection.

Life sciences Behavioural & social sciences Ecological, evolutionary & environmental sciences

For a reference copy of the document with all sections, see nature.com/documents/nr-reporting-summary-flat.pdf

Life sciences study design

All studies must disclose on these points even when the disclosure is negative.

Sample size	n=2244 critically ill Covid-19 patients, n=11220 random controls matched by ancestry from UK Biobank. The sample size was determined pragmatically by the number of cases recruited during the first wave of the outbreak in the UK. Adequate statistical power was determined by the detection of significant associations, and is confirmed by replication in external studies.
Data exclusions	Patients of mixed genetic ancestry, and from ancestry groups with small numbers of cases (such as North American Indian) defined using principal components analysis, were excluded because we were not able to match adequate controls for these individuals.
Replication	Replicated main findings using 2415 hospitalised Covid-19 patients and 477741 population controls from Covid19 Host genetics initiative and 1128 Covid19 cases and 679531 population controls from 23andme Inc "broad respiratory" phenotype. 3 variants did not replicate; all are in the MHC region, which is both highly sensitive to population stratification (potentially causing spurious associations) and commonly associated with infectious and immune disease.
Randomization	Not relevant to the study. There wasn't any allocation to experimental groups
Blinding	Blinding was not used in this study because the exposure (genotype) and outcome (ICU admission) are objective. Confounding was controlled by the use of covariates: age, sex, deprivation score and genetic ancestry (principal components).

Reporting for specific materials, systems and methods

We require information from authors about some types of materials, experimental systems and methods used in many studies. Here, indicate whether each material, system or method listed is relevant to your study. If you are not sure if a list item applies to your research, read the appropriate section before selecting a response.

Human research participants

Policy information about [studies involving human research participants](#)

Population characteristics	1574 males, 670 females. 1176 European ancestry, 227 South Asian ancestry, 182 African ancestry, 149 East Asian ancestry. Mean age is 57.3 years
Recruitment	Critically-ill cases were recruited through the GenOMICC study in 208 UK Intensive Care Units and hospitalised cases through the International Severe Acute Respiratory Infection Consortium (ISARIC) Coronavirus Clinical Characterisation Consortium (4C) study. Genomicc patients ha confirmed Covid-19 according to local clinical testing and were deemed by the treating physician to require continuous cardiorespiratory monitoring in intensive care units. ISARIC4C individuals had confirmed Covid-19 and were deemed to require hospital admission. Since this outcome is determined by clinicians it is unlikely to be affected by self-selection bias.
Ethics oversight	Research ethics committees (Scotland 15/SS/0110, England, Wales and Northern Ireland: 19/WM/0247. Current and previous versions of the study protocol are available at genomicc.org/protocol . All participants gave informed consent.

Note that full information on the approval of the study protocol must also be provided in the manuscript.
